Parity nonconservation due to the nuclear weak charge is considered. We demonstrate that the radiative corrections to this effect due to the vacuum fluctuations of the characteristic size larger than the nuclear radius r_0 and smaller than the electron Compton wave-length λ_C are enhanced because of the strong electric field of the nucleus. The parameter that allows one to classify the corrections is the large logarithm $\ln(\lambda_C/r_0)$. The vacuum polarization contribution is enhanced by the second power of the logarithm. Although the self-energy and the vertex corrections do not vanish, they contain only the first power of the logarithm. The value of the radiative correction is 0.4% for Cs and 0.9% for Tl, Pb, and Bi. We discuss also how the correction affects the interpretation of the experimental data on parity nonconservation in atoms.

PACS: 32.80.Ys, 11.30.Er, 31.30.Jv

Atomic parity nonconservation (PNC) has now been measured in bismuth [1], lead [2], thallium [3], and cesium [4]. Analysis of the data provides an important test of the Standard Electroweak model and imposes constraints on new physics beyond the model, see Ref. [5]. The analysis is based on the atomic many-body calculations for Tl, Pb, and Bi [6] and for Cs [7,8]. Both the experimental and the theoretical accuracy is best for Cs. Therefore, this atom provides the most important information on the Standard model in the low energy sector. The analysis performed in Ref. [4] has indicated a deviation of the measured weak charge value from that predicted by the Standard model by 2.5 standard deviations σ .

In the many-body calculations [6–8] the Coulomb interaction between electrons was taken into account, while the magnetic interaction was neglected. The contribution of the magnetic (Breit) electron-electron interaction was calculated in the recent papers [9,10]. It proved to be much larger than a naive estimate, and it shifted the theoretical prediction for PNC in Cs. As a result, the deviation from the Standard model has been reduced. The calculations [9,10] have already been used to get new restrictions on possible modifications of the Standard model, see, e. g., Ref. [11]. The reason for the enhancement of the Breit correction has been explained in Ref. [12]. In the case of the Coulomb residual interaction the effect of the many-body polarization is maximum for the outer electronic subshell and quickly drops down inside the atom [6–8]. The Breit interaction is more singular at small distances than the Coulomb one. Hence, the polarization is maximum for the lowest subshell ($1s^2$) and quickly drops down towards the outer shells. The estimate of the relative effect of the magnetic polarization gives $Z\alpha^2$ instead of naive α^2 , where Z is the nuclear charge and α is the fine structure constant. To find the Breit correction there is no need to repeat the involved many-body calculations performed in Refs. [6–8]. Indeed, the Breit correction comes from small distances,

$r \sim a_B/Z$ (a_B is the Bohr radius), while all the Coulomb polarization and correlation corrections come from large distances, $r \sim a_B$. Therefore, it is sufficient to calculate the relative Breit correction to some PNC mixing matrix element (say $6s_{1/2} - 6p_{1/2}$ mixing in Cs) in the simplest Hartree-Fock or RPA approximation. The relative Breit correction to the PNC effect with account of all many-body Coulomb polarization and correlation corrections is exactly the same.

The Breit correction to PNC is just a part of the effect. This part is related to the virtual excitations of the $1s^2$ subshell. Another contribution comes from the vacuum fluctuations, i.e. from the radiative corrections. Attempts to estimate this effect were made in Ref. [13] and gave very small values of the corrections. It has been pointed out recently [12] that the strong electric field of the nucleus enhances the radiative corrections, and they may be comparable with the Breit correction. Very recently this suggestion has been confirmed by the numerical calculation of the vacuum polarization correction in Cs [14].

In the present paper we consider PNC in heavy atoms and calculate radiative corrections enhanced by the strong electric field of the nucleus. We calculate analytically the leading term in the correction and we also estimate other terms. It turns out that in Cs, Tl, Pb, and Bi the radiative correction compensates the Breit correction calculated in Refs. [9,10]. Thus, we return back to the result of the experimental data analysis made in Ref. [4]: deviation from the Standard model is 2.2 - 2.3 σ .

In the Standard model it is accepted to normalize the Weinberg angle at the W-boson mass M_W . Atomic experiments correspond to a very low momentum transfer compared to M_W . The renormalization from M_W to zero momentum transfer was performed in Refs. [15,16]. This renormalization is reduced to the logarithmically enhanced single loop corrections $\propto \alpha/\pi$ that lead to what is usually called the radiative correction to the nuclear weak

charge. Account of this very important correction gives the nuclear weak charge Q_W measured in on-mass-shell electron scattering at zero momentum transfer, where $p^2 = m^2$ and $q = 0$. However, atomic PNC corresponds to a different situation. The electron in the strong nuclear electric field is off the mass-shell, $p^2 \sim 1/r_0^2 \gg m^2$ and, besides, the typical momentum transfer is of the order of the inverse nuclear radius, $q \sim 1/r_0$. In a precise calculation these effects must be taken into account. It is convenient to use Q_W calculated in Refs. [15,16] as a reference point. Then the renormalization procedure is the same as that in quantum electrodynamics and the correction vanishes on mass shell at zero momentum transfer. In this approach it is clear that the correction we are talking about is somewhat similar to the radiative correction to the hyperfine constant in a heavy atom [17].

The wave function of the external electron is of the form

$$u(\mathbf{r}) = \begin{pmatrix} F(r)\Omega \\ iG(r)\tilde{\Omega} \end{pmatrix}, \quad (1)$$

where Ω and $\tilde{\Omega} = -(\boldsymbol{\sigma} \cdot \mathbf{n})\Omega$ are spherical spinors [18]. At small distances $r \ll Z\alpha\lambda_C$, where λ_C is the electron Compton wave-length, the electron mass is small compared to the nuclear Coulomb potential, and the radial wave functions obey the equations

$$\begin{aligned} \frac{d(rF)}{dr} + \frac{\kappa}{r}(rF) - \frac{Z\alpha}{r}(rG) &= 0, \\ \frac{d(rG)}{dr} - \frac{\kappa}{r}(rG) + \frac{Z\alpha}{r}(rF) &= 0. \end{aligned} \quad (2)$$

For PNC effect we need to consider only $s_{1/2}$ ($\kappa = -1$) and $p_{1/2}$ ($\kappa = +1$) electron states. Solution of Eqs. (2) reads

$$F = Ar^{\gamma-1}, \quad G = A \frac{Z\alpha}{\kappa - \gamma} r^{\gamma-1}, \quad (3)$$

where $\gamma = \sqrt{1 - Z^2\alpha^2}$ and A is some constant dependent on the wave function behavior at large distances ($r \sim a_B$) [19]. In the leading approximation the PNC interaction

FIG. 1. The leading contribution and the radiative corrections to the PNC effect. The double line is the exact electron Green's function in the Coulomb field of the nucleus, the cross denotes the nucleus, the zigzag and the dashed lines denote Z-boson and photon, respectively.

related to the weak charge is due to Z-boson exchange, see Fig.1a. Calculation of the corresponding weak interaction matrix element gives [19]

$$\langle p_{1/2} | H_W | s_{1/2} \rangle = M_0 \propto (F_s G_p - G_s F_p) |_{r=r_0}. \quad (4)$$

At $r_0 \rightarrow 0$ this matrix element is divergent, $M_0 \propto r_0^{2\gamma-2}$. As a result, the relativistic enhancement factor is $R \approx 3$ for Cs and $R \approx 9$ for Tl, Pb, and Bi [19]. In the present paper we show that this divergence results in the double logarithmic enhancement of the radiative corrections.

The first correction is shown in Fig.1b. It corresponds to a modification of the electron wave function because of the vacuum polarization. In the leading $Z\alpha$ approximation the vacuum polarization results in the Uehling potential [20]. At $r \ll \lambda_C$, this potential is of the form $V(r) \approx 2Z\alpha^2 [\ln(r/\lambda_C) + C + 5/6] / (3\pi r)$, where $C \approx 0.577$ is the Euler constant. Account of higher in $Z\alpha$ corrections in the vacuum polarization leads to a modification of the constant: $C \rightarrow C + 0.092Z^2\alpha^2 + \dots$, see Ref. [21]. However, this correction is small and can be neglected even for $Z\alpha \sim 1$. The potential $V(r)$ modifies the Coulomb interaction in Eqs. (2) $-Z\alpha/r \rightarrow -Z\alpha/r + V(r)$. It is convenient to search for solution of the modified Eqs. (2) in the following form $\mathcal{F} = F(1 + F^{(1)})$, $\mathcal{G} = G(1 + F^{(1)})$, where F and G are given by (3). The functions $F_{s,p}^{(1)}$ and $G_{s,p}^{(1)}$ satisfy the following equations

$$\begin{aligned} \frac{1}{\gamma + \kappa} \frac{dF^{(1)}}{dx} - F^{(1)} + G^{(1)} &= -\frac{2\alpha}{3\pi} x \\ \frac{1}{\gamma - \kappa} \frac{dG^{(1)}}{dx} - G^{(1)} + F^{(1)} &= -\frac{2\alpha}{3\pi} x, \end{aligned} \quad (5)$$

where $x = \ln(\lambda/r)$, and $\lambda = \lambda_C \exp(-C - 5/6)$. The solution of these equations reads

$$\begin{aligned} F^{(1)} &= \frac{\alpha}{3\pi} \left[\frac{(Z\alpha)^2}{\gamma} x^2 + \frac{\kappa(\gamma + \kappa)}{\gamma^2} x + \frac{\kappa}{2\gamma^2} + a \right] \\ G^{(1)} &= \frac{\alpha}{3\pi} \left[\frac{(Z\alpha)^2}{\gamma} x^2 - \frac{\kappa(\gamma - \kappa)}{\gamma^2} x - \frac{\kappa}{2\gamma^2} + a \right], \end{aligned} \quad (6)$$

where a is some constant. Using $\mathcal{F}$ and $\mathcal{G}$ instead of F and G in Eq. (4) we obtain the PNC matrix element in the form

$$\langle p_{1/2} | H_W | s_{1/2} \rangle = M_0 (1 + \delta), \quad (7)$$

where δ due to the diagram Fig.1b is

$$\delta_b = \frac{1 + \gamma}{2} (F_s^{(1)} + G_p^{(1)}) + \frac{1 - \gamma}{2} (F_p^{(1)} + G_s^{(1)}). \quad (8)$$

To find the correction δ_b with the logarithmic accuracy there is no need to calculate a in Eqs. (6), it is enough to substitute the logarithmic terms from (6) into (8). An analysis that also includes a consideration of distances $r \sim \lambda_C$ gives

$$\delta_b = \alpha \left(\frac{1}{4} Z\alpha + \frac{2(Z\alpha)^2}{3\pi\gamma} [\ln^2(b\lambda_C/r_0) + B] \right), \quad (9)$$

where $b = \exp(1/(2\gamma) - C - 5/6)$, and $B \sim 1$ is some smooth function of $Z\alpha$ independent of r_0 . A numerical calculation of δ_b for Cs was performed recently in Ref. [14]. The result is in a good agreement with Eq. (9). Comparison of Eq. (9) with the result of Ref. [14] allows also to determine B : $B \approx 1$. We would like to emphasize that Eq. (9) does not assume that $Z\alpha \ll 1$, it is valid for any $Z\alpha < 1$. Note that the $(Z\alpha)^2$ term in (9) is larger than the $Z\alpha$ one at $Z > 10$.

We already pointed out that the weak charge calculated in Refs. [15,16] corresponds to zero momentum transfer. On the other hand, it is clear from Eq. (4) that the weak interaction matrix element is determined by the momentum transfer $q \sim 1/r_0$. The renormalization of the weak charge from $q = 0$ to $q \sim 1/r_0$ is described by diagrams c and d in Fig.1. A simple calculation gives the following correction $\delta Q_W/Q_W = \delta_{cd}$ related to this renormalization

$$\delta_{cd} = \frac{4\alpha Z}{3\pi Q_W} (1 - 4 \sin^2 \theta_W) \ln(\lambda_C/r_0) \approx -0.1\%. \quad (10)$$

Where $\theta_W \approx$ is the Weinberg angle, $\sin^2 \theta_W \approx 0.2230$, see Ref. [5]. Note that this correction is practically independent of Z because $Z/Q_W \approx -Z/N \approx -0.7$, where N is the number of neutrons. One can also obtain the correction (10) using Eqs. (2a,b), and (3b) from Ref. [15].

Next we consider the contribution of the electron self-energy operator Σ . This operator being substituted to the Dirac equation, $m \rightarrow m + \Sigma$, leads to the Lamb shift of the energy level and to the modification of the electron wave function, see, e.g., Ref. [18]. As shown in Fig.1e, this modification influences the matrix element of the weak interaction. The diagram Fig.1e is not invariant with respect to the gauge transformations of the electromagnetic field. However, the sum of the diagrams Fig.1e and Fig.1f (the vertex correction) is gauge invariant. It is convenient to represent the self energy operator as a series in powers of the Coulomb field of the nucleus, $\Sigma = \Sigma_0 + \Sigma_1 + \Sigma_2 + \dots$, see Fig.2.

FIG. 2. The electron self energy expanded in powers of the Coulomb field. The solid line is the free electron Green's function, the cross denotes the nucleus, and the dashed line denotes the photon.

We need $\Sigma(\mathbf{r}, \mathbf{r}'|\epsilon)$ at $r \sim r' \ll \lambda_C$, $\epsilon \approx m$. In this limit a calculation in the Feynman gauge with logarithmic accuracy gives

$$\Sigma_0 = \hat{p} \frac{\alpha}{4\pi} \ln(p^2/m^2), \quad \Sigma_1 = \frac{Z\alpha^2}{4\pi r} \gamma_0 \ln(p^2/m^2), \quad (11)$$

where $\hat{p} = p^\mu \gamma_\mu$, γ_μ is the Dirac matrix, and p^μ is the momentum operator. All the higher terms are not logarithmically enhanced. Further calculation in Feynman gauge is rather involved because the diagram Fig.1f is also logarithmically enhanced and there is a delicate cancellation between a part of the Σ -contribution and the logarithmic part of Fig.1f. To avoid all these complications it is convenient to use the Landau gauge. In this gauge neither Σ_n ($n = 0, 1, 2, \dots$) nor the contribution of Fig.1f contain the large logarithm $\ln(\lambda_C/r_0)$. Therefore, after the renormalization, taking zero momentum transfer as a reference point, the contribution of Fig.1f is of the form $\delta_f \sim Z\alpha^2(1 + fZ\alpha/\pi + \dots)$, where we expect $f \sim 1$. Since Σ does not contain logarithms, at $r \ll \lambda_C$ we have $\Sigma u = (Z\alpha^2/\pi r) \mathcal{D}u$, where $\mathcal{D} \sim 1$ is some matrix dependent on $Z\alpha$, and u is the electron wave function. Substitution of Σu into the Dirac equation results in the x -independent terms of the order of $\sim \alpha/\pi$ in the right hand sides of Eqs. (5). As a result, the relative correction to the matrix element of the weak interaction due to the diagram Fig.1e contains logarithmically enhanced $Z^2\alpha^3$ terms. There is also a $Z\alpha^2$ contribution coming from the distances $r \sim \lambda_C$. All in all the total contribution of diagrams Fig.1e and Fig.1f is of the form

$$\delta_{ef} = Z\alpha^2 \left[a_1 + a_2 \frac{Z\alpha}{\pi} \ln(\lambda_C/r_0) \right]. \quad (12)$$

Our preliminary estimate gives $a_1 \approx 0.15$, and we expect $a_2 \sim 1$. Therefore, the value of δ_{ef} for Cs is $\delta_{ef} \sim 0.1\%$. The calculation of the coefficient a_2 in Eq. (12) is a very interesting and challenging problem. At this stage we can claim only that the contribution (12) is much smaller than that of the Uehling potential (9) because it does not contain the big logarithm squared.

There is one more radiative correction that has never been considered before. This contribution is due to the virtual excitation of the nuclear giant dipole resonance A^* shown in Fig.3.

FIG. 3. Virtual excitation of the giant nuclear resonance.

Our estimate gives

$$\delta_{A^*} \approx -0.1 Z^{2/3} \alpha^2. \quad (13)$$

So it is completely negligible.

Considering all the corrections, one has to remember about the contribution of the electron-electron weak interaction. Although this is not a radiative correction, we

still denote it δ_{e-e} . According to Ref. [22] this correction is

$$\delta_{e-e} \approx \frac{0.56}{ZR(Z)}(1 - 4 \sin^2 \theta_W), \quad (14)$$

where $R(Z)$ is the relativistic enhancement factor defined in Ref. [19]. Values of R are presented after Eq. (4). For Cs the δ_{e-e} -correction is +0.04%, so it is also negligible.

In summary, we have calculated radiative corrections to the parity nonconservation effects in atoms due to the strong electric field of the nucleus. The structure of the correction is somewhat similar to that for the radiative correction to the hyperfine interaction [17]. However there are two essential differences. 1) The corrections to the PNC effects are enhanced by the large logarithm dependent on the nuclear radius. 2) The contribution of the Uehling potential to the PNC radiative correction is dominating because it contains the second power of the logarithm, see Eq. (9). The vertex and the self-energy corrections do not vanish, but they are not enhanced by the second power of the logarithm. The vertex, self-energy, nuclear excitations, and the electron-electron corrections, see Eqs. (10), (12), (13), and (14), contribute at the level $\pm 0.1\%$.

The correction (9) has been derived for the electron-nucleus weak interaction independent of the nuclear spin, i. e. for the weak charge Q_W . However, the same formula is valid for the PNC effect dependent on the nuclear spin, i. e. for the anapole moment. This is obvious because the anapole moment interaction is also local, see Ref. [19].

The radiative correction (9) is +0.4% for Cs and +0.9% for Tl, Pb and Bi. The value of the Breit correction in Cs is -0.6%, see Refs. [9,10]. The Breit correction scales practically linearly with Z , see Ref. [12]. Therefore, for Tl, Pb, and Bi the value of the Breit correction is -0.9%. Thus, the radiative correction compensates the great part of the Breit correction in Cs, and practically exactly compensates it in Tl, Pb, and Bi. With account of both corrections, the difference between the Standard model prediction and the experimental result in Cs, see Ref. [4], stays at the level of 2.2σ .

Concluding we would like to say that both the radiative and the Breit corrections presently are known with high accuracy and this accuracy can be even further improved. The present limitation of the accuracy in the atomic calculations comes from many-body effects with pure Coulomb electron-electron interaction considered in Refs. [7,8]. An improvement of the accuracy of these calculations is a feasible but a very challenging problem.

A.I.M. would like to thank M. G. Kozlov for helpful discussions, and the School of Physics at the University of New South Wales for warm hospitality and financial support (Gordon Godfrey fund) during a visit.
